ABSTRACT

This paper describes the VIS processing function (VIS PF) of the *Euclid* ground segment pipeline, which processes and calibrates raw data from the VIS camera. We present the algorithms used in each processing element, along with a description of the on-orbit performance of VIS PF, based on performance verification (PV) and Q1 data. We demonstrate that the principal performance metrics (image quality, astrometric accuracy, photometric calibration) are within pre-launch specifications. The image-to-image photometric scatter is less than $0.8\,\%$ and absolute astrometric accuracy compared to Gaia is 5 mas. Image quality is stable over all Q1 images with a full width at half maximum (FWHM) of $0\!\!''\!16$. The stacked images (combining four nominal and two short exposures) reach $I_{\rm E} = 25.6$ ($10\,\sigma$, measured as the variance of $1\!\!''\!3$ diameter apertures). We also describe quality control metrics provided with each image and an appendix provides a detailed description of the provided data products. The excellent quality of these images demonstrates the immense potential of *Euclid* VIS data for weak lensing. VIS data, covering most of the extragalactic sky, will provide a lasting high-resolution atlas of the Universe.

Key words. Cosmology: observations – space vehicles: instruments – instrumentation: detectors – surveys – Techniques: imaging spectroscopy – Techniques: photometric

1. Introduction

The ESA *Euclid* mission ([Laureijs et al. 2011](#)), launched in July 2023, aims to significantly improve constraints of the dark energy equation of state ([Euclid Collaboration: Mellier et al. 2024](#)). *Euclid* will achieve this by combining near-infrared spectroscopic redshifts that trace structures on large scales across cosmic time with optical galaxy-shape measurements that provide information on the distribution of dark matter.

At the heart of *Euclid* are two instruments, VIS ([Euclid Collaboration: Cropper et al. 2024](#)) and NISP ([Euclid Collaboration: Jahnke et al. 2024](#)), which can observe the sky simultaneously in the optical and the near-infrared using a dichroic beamsplitter. The Euclid Wide Survey (EWS) [Euclid Collaboration: Scaramella et al. 2022](#)) uses these instruments to cover the darkest $14\,000\,{\rm deg}^2$ of the extragalactic sky, producing tens of thousands of images. The shapes and positions of billions of galaxies are extracted from these images using automated pipelines that run in a distributed processing environment known as the 'Science Ground Segment'. The Euclid Deep Survey (EDS) and auxiliary calibration fields comprise a set of smaller sky areas that are observed to forty times the depth of the EWS. These fields provide an essential check for the quality of the ground segment processing.

Euclid's ambitious requirements place stringent constraints on the number of galaxies that must be observed, the accuracy with which their shapes can be measured, and therefore our knowledge of the telescope's point spread function (PSF) (see [Massey et al. 2013](#) and [Cropper et al. 2013](#) for an early description of how the *Euclid* requirements were derived). This in turn requires a meticulous approach in data processing. This paper describes one of the earliest stages of the ground-segment pipeline: the set of processing elements that takes raw VIS images and produces scientifically validated and calibrated images, on which photometric and shape measurements can be made. In particular, we describe the algorithmic choices we have made for each of the different instrumental effects that must be characterised and calibrated. We demonstrate the performance of each element individually where possible, as well as the measured performance on the first public release of data from the ground segment, the Quick Release 1 ([Euclid Collaboration: Aussel et al. 2025](#); [Euclid Quick Release Q1 2025](#)).

2. The VIS instrument

In contrast to general-purpose observatories such as the *Hubble* Space Telescope (HST), which are designed for a range of different science cases, the ambitious *Euclid* mission requirements described above drive the entire design of the VIS camera. The primary requirement is to have the best possible image quality over the largest possible field of view with minimal temporal variation. This in turn specifies the field of view of the VIS camera, the pixel scale, the exposure time for each observation, the survey duration and scheduling as well as many other aspects of the spacecraft ([Euclid Collaboration: Cropper et al. 2024](#)).

2.1. The VIS camera and detectors

The VIS focal-plane array (FPA) comprises 36 back-illuminated $40\,\mu{\rm m}$-thick charge-coupled devices (CCDs) each 4132×4096 pixels in size. Each pixel is $12\,\mu{\rm m} \times 12\,\mu{\rm m}$. At the centre of the FPA, the pixel scale is $\sim 0\!\!''\!1$. The variation in intrinsic pixel

---

size is less than 1%. There are four readout nodes (with separate electronics), one at each corner of the CCD. The e2v device CCD273-84 used was designed specifically for VIS. There are 51 serial prescan pixels, 29 serial overscan pixels, and 20 parallel overscan pixels. The prescan pixels are real pixels not exposed to light. The overscan pixels, whether serial or parallel, do not correspond to imaging pixels and are generated by overclocking the detector. These overscan regions enable the estimation of the pedestal level added by the detector electronics.

The non-ionising effects of particle radiation on silicon detectors has been a significant concern since the mission was proposed. Energetic particles can produce defects in the silicon lattice that increase the charge-transfer inefficiency (CTI). The VIS detectors contain a charge-injection structure in the middle of the device, allowing an arbitrary amount of charge to be introduced in a CCD, which can then subsequently be read out (see figure 11 in Euclid Collaboration: Cropper et al. 2024). The modelling and correction of CTI using this charge-injection procedure is described in detail in Sect. 3.8. The presence of the charge-injection lines means that a distortion model must be computed separately for each quadrant. For this reason, all calibrated images (or 'frames') are delivered as a multi-extension FITS (MEF) file with 144 extensions, one per quadrant. Figure 1 shows the position of each quadrant in the FPA in millimetres, labelled with its identifier and extension number.

Fig. 1. The layout of quadrants in the FPA. The detectors, each containing four quadrants, are arranged in a 6×6 array. The mean CCD spacing is (1.53 ± 0.03) mm and (7.74 ± 0.06) mm in the x- and y-directions, respectively.

3. The VIS processing function: corrections made at the pixel level

3.1. Overview

The VIS PF is divided into two main functional units: a 'calibration pipeline' that computes the master calibration products for each of the instrumental effects, and a 'science pipeline' that ap-
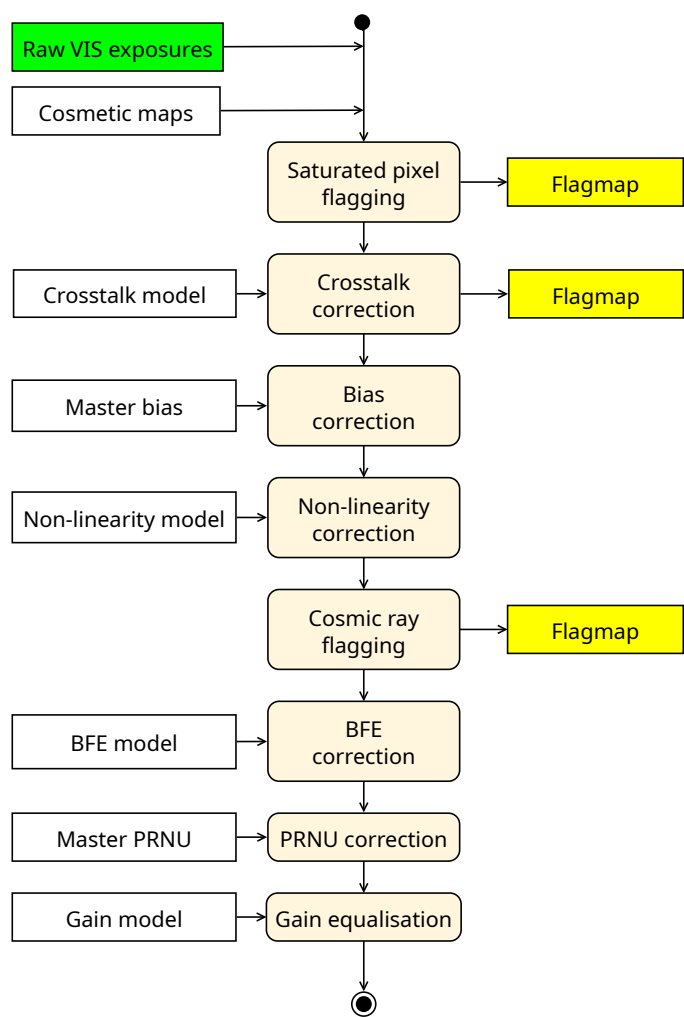

Fig. 2. The first elements in the VIS PF. Input calibration products are shown on the left and output flagmaps are on the right. 'BFE' refers to the brighter-fatter effect (Sect. 3.9) and 'PRNU' is the pixel response non-uniformity (Sect. 3.10). We note that CTI correction is not activated in Q1 processing due to limited radiation damage at this stage of the mission, and therefore is not shown.

plies each of these corrections to the raw VIS data. Here we describe the calibration and correction of each of these instrumental effects in the order they are applied in the science pipeline. Before launch, VIS PF was developed, tested, and validated by processing highly realistic simulated raw VIS data (Euclid Collaboration: Serrano et al. 2024), created using the best available ground-calibration data.

To understand the functionality required from VIS PF, it is worth briefly describing the reference observing sequence (ROS) (Euclid Collaboration: Scaramella et al. 2022; Euclid Collaboration: Mellier et al. 2024) executed at every location in the EWS. Each ROS consists of four dithers in an 'S'-pattern, where VIS and NISP observe simultaneously. At each dither, VIS takes a 566 s 'nominal science' exposure. The first two dithers also contain an additional 95 s VIS 'short science' exposure, and calibration exposures fill the remaining two dithers.[1] While the EWS

---

[1] As a consequence of the shutter motion, the exposure times of 560.52 s and 89.52 s for short and long exposures (reported as EXPTIME in the image headers) corresponds to the time the shutter is fully open. In a given image, the total exposure per pixel varies over the field of view. See Sect. 4.4 for more details.

comprises a single ROS at each pointing, the EDS fields are visited at least 40 times in a manner similar to the EWS at a range of roll angles. The VIS PF must therefore provide calibrations for both the nominal and short-science exposures.

A brief note on terminology: the term 'processing element' (PE) refers to a sub-element of the VIS PF . Normally, the scope of a given processing element is limited. The term 'processing function' refers to the ensemble of PEs that makes up the entire pipeline. In our case, VIS PF refers to the sequence of PEs that comprise the VIS processing pipeline.[2] We note here that the principal client processing functions for VIS PF are the shear processing function, 'SHE-PF', which measures shapes on individual VIS images, and the MER processing function (MER PF) (Euclid Collaboration: Romelli et al. 2025, which combines data from *Euclid* instruments with external data. MER PF takes as input from VIS PF the calibrated images described here and an associated PSF model.

In operations, the main VIS PF science pipeline (`VIS_ProcessField`) is run on every raw science VIS exposure. It applies all the instrumental corrections in the order described below. This pipeline must be robust against bad or incomplete data, and it must also flag data so downstream PFs can apply selection functions if needed. Additionally, given the large number of VIS exposures arriving each day (around 156 during nominal wide-survey acquisitions), data must be processed quickly. This is because downstream PFs also have significant computational requirements, and the ground segment must be able to process all data from a given day's observations before the next day's data arrive.

The VIS PF is large and contains many processing elements. In the interests of simplicity, we divide the processing function into three sections. In the first part, described in this section and shown schematically in Fig. 2, pixel-level corrections are carried out on the individual quadrants. In general, each quadrant is treated independently. Next, as described in Sect. 4 and shown schematically in Fig. 7, catalogues are extracted from the processed quadrants and are used to compute the astrometric and photometric solutions. This stage provides the calibrated exposures that are used by SHE and MER processing functions. In the final stage, described in Sect. 5 and shown in Fig. 14, we combine the individual calibrated frames from a ROS to make a stacked image.

3.2. VIS LE1 processing

Although not strictly part of the VIS PF, for completeness we provide here a high-level summary of the software we developed to assemble the raw data from the VIS camera into MEF files, the VIS 'Level 1' or LE1 processor. This software runs at the Science Operations Centre (SOC) and unpacks the compressed raw data transmitted from the spacecraft into a MEF file with 144 extensions. The image metadata is processed from either the raw VIS data or other general housekeeping telemetry, and placed into the FITS headers with specific keywords. The primary header of the MEF contains information specific to the whole image, such as the observation date, image acquisition parameters, instrument temperatures, and spacecraft pointing and attitudes. The header of each extension does not contain much information at this stage, apart from a few quadrant-specific pa-

rameters and the data compression ratio for the quadrant. It also contains a preliminary astrometric solution based on the commanded pointing values, RA, Dec, position angle (PA), and the FPA geometry (pixel size, dimensions, and layout of the detectors).

3.3. Bad pixel flagging

It is paramount for downstream processing functions that VIS PF can correctly indicate the characteristics of each pixel in the individual calibrated frames. For this reason, each VIS calibrated image is accompanied by a flag (FLG) FITS file. Each pixel of this image is coded based on the processing during the VIS PF ; a full description of the meaning of these flags is found in Appendix A.1. Below, we provide a brief overview of the primary artefacts identified in the images:

– **Analogue-to-digital converter (ADC) limit**. Data in VIS raw frames are integers produced by 16-bit ADCs that have an output range from 0 to 65 535 analogue-to-digital unit (ADU). Any pixel at this maximum value is flagged as invalid because its actual value can be above this limit.

– **Saturated pixels**. Blooming can occur in thick CCDs (such as those used in VIS) when the charge is still below the full-well capacity of the CCD creating a similar effect as saturation bleeding. Above the blooming threshold, the charges in a pixel begin to overflow in the neighbour pixels in the same column. The value of this blooming threshold is different for each quadrant, and must be determined. The blooming-threshold calibration involves the computation of the photon transfer curve (PTC), which is the relationship between the signal and its variance. Pairs of flat-fields at different fluences are subtracted to remove the lamp profile on the flat-fields, then the PTC is created by computing the average signal and variance of the difference of the flat-fields in regions of 300×300 pixels. Once the brighter-fatter effect (BFE) and electronic nonlinearity are corrected (described later), we expect the relation to follow Poisson statistics, and therefore the variance equals the mean signal divided by the gain. The blooming threshold is then defined as the ADU value above which the nonlinearity of the relation between signal and variance exceeds 5%. Blooming values range from 40 kADU to 61 kADU with a mean of 51 kADU.

– **Hot and dark pixels**. Abnormally bright or dark pixels are detected in master dark and flat frames as pixels with a mean value deviating by more than six or seven standard deviations from the master frame mean value.

– **Stitch-block boundaries.** This flag indicates the boundaries between different 'stitch blocks'. The photolithographic mask used in the manufacturing of the CCD273-84 exposes a block of 512×256 pixels at a time. Therefore, the mask is applied consecutively to the whole CCD area, resulting in blocks that are stitched together. The positions of these blocks were identified from ground tests.

– **Bad cluster and columns**. In flat-field images, bad pixels are often surrounded by a cluster of brighter or darker than average pixels. This is true for both dust particles and electronic defects. Such clusters are detected by iteratively searching for a minimum of three nearest neighbours to a bad pixel or neighbour of a bad pixel, with a threshold of ±2 standard deviations. An entire column is flagged as bad if it has more than 200 bad pixels in a master dark.

3.4. Crosstalk measurement and correction

In the VIS instrument, electronic crosstalk occurs because all twelve quadrants (four in each of the three CCDs) of the same readout electronic block unit (ROE) are read synchronously in parallel. The signal in each quadrant receives a positive or negative contribution from potentially all other channels within the same ROE through undesired capacitive or inductive coupling. This contribution is up to 5×10^{-4} times the source quadrant signal.

This effect is more significant when the electronic components of the quadrant channel are in proximity to another on the ROE boards. The value of the positive or negative coupling factor for each pair of source/victim quadrants is called the electronic crosstalk coefficient. There are 12 victim $\times$ 11 source quadrant pairs in each one of the 12 ROE blocks, which amounts to a total of 1584 crosstalk coefficients that must be measured and corrected for in VIS images.

To measure a crosstalk coefficient, we select unsaturated pixels in a source/victim quadrant pair. Pixels in the source quadrant must contain a high signal (more than 10 000 ADU) and the corresponding pixels in the victim quadrant and in the other quadrants of the ROE must belong to the sky background. After background subtraction in the victim quadrant, the crosstalk coefficient is measured as the linear regression factor between the pixel values in the victim quadrant and the same pixel values in the source quadrant. Adding more exposures adds more source/victim pixel pair statistics and reduces measurement noise.

Once the 1584 crosstalk coefficients have been estimated, the electronic crosstalk correction in the science pipeline consists in subtracting, for a given victim quadrant image, the image of each source quadrant multiplied by the corresponding (positive or negative) crosstalk coefficient.

The largest crosstalk effect in a victim quadrant is around 30 ADU from an almost-saturated source pixel. If a source pixel value saturates the ADC (65 535 ADU), its 'true' value that created the crosstalk effect is unknown, and all the corresponding victim pixels must therefore be invalidated.

The electronic crosstalk correction in the VIS science pipeline has two limits. First, to avoid mixing too many signals and adding noise or correlations, the crosstalk correction is not applied when the corresponding coefficient is under 4×10^{-5} (a maximum effect of about 2.6 ADU). Furthermore, we found that in addition to the linear effect currently measured and corrected, a differential effect also exists when sharp rising or falling edges occur in the source signal. This differential effect could amount to approximately 5 ADU.

3.5. Bias and dark

The bias correction has two components. The first is the average pixel value of a quadrant relative to zero. This offset is expected to be a few thousand ADUs and is a single number per quadrant. This offset can be considered constant during the 72 s readout, but has a long-term time dependency, and therefore it must be independently measured in every VIS exposure from the overscan pixels described above, which should not be contaminated by any signal source apart from readout noise. A second bias correction is made using a master bias image. This image captures the spatial, per-pixel dependence of the bias relative to the constant offset. The master bias image is computed from a median combination of at least 60 individual offset-corrected bias frames. These are zero-seconds, closed-shutter exposures. The bias is an additive offset, and therefore each exposure is bias-subtracted.

Dark frames with 325 s integration time are also taken, and subsequently combined into master-dark frames. Cosmic rays (CRs) detected in the individual dark frames are also used to produce a library of real CRs that can be used to generate survey images with simulated CRs, necessary to test the CR detection software described in Sect. 3.7.

Finally, shortly after launch, it was discovered that VIS images are affected in varying amounts by stray light (see Sect. 5.4 in Euclid Collaboration: Mellier et al.). The master darks are used to assess the importance of stray light for a given set of exposures at a given solar aspect angle and telescope orientation.
3.6. Nonlinearity measurement and correction

During the CCD quadrant readout, the charge from all pixels passes through the quadrant's output node and readout electronics. However, because of limitations of the readout amplification chain, output digitised values may deviate slightly from perfect proportionality to the input charge. This effect, known as nonlinearity, may be as large as a few percent at high signal levels. Without correction, this would introduce an additional source of error in the measurement of the PSF, as these measurements are carried out on bright sources with high signal-to-noise ratios. Simulations carried out before launch indicated that nonlinearity should be known to better than one part in 6×10^{-4} to meet the requirements on PSF measurement at fluences above approximately $10 \, \mathrm{k \, e^-}$.

Conceptually, correcting this nonlinearity effect is straightforward: measure the response in ADUs for a linear source of photons. Before launch, several algorithms were tested with simulated data to make this measurement. However, due to the presence of CRs and telescope jitter, these techniques could not deliver the percent-level accuracy required in real data. Work in perfecting these algorithms is still in progress.

However, during ground testing, we investigated an alternative technique that uses the light-emitting diodes (LEDs) of the VIS calibration unit (CU). As described in Sect. 3.10, these diodes are used to illuminate the FPA to calibrate the PRNU. The linearity and photometric stability of these had not been specified for the VIS. However, ground testing in 2021 showed that over a one-hour timescale, the LED output varies by less than one part in 10^4, indicating that this technique could be a viable method to correct for nonlinearity. Therefore, an experiment was designed to measure the nonlinearity during on ground testing by illuminating the FPA with pulses of different length in a random order of calibration unit LED 3 (720 nm) and then reading out a windowed section of each detector. The nonlinearity of each channel was derived by determining the deviation of the signal from a linear function of the LED pulse time, assuming a constant LED intensity. Above 300 ADU and until about 1000 ADU, the signal is approximately linear. An example nonlinearity measurement is shown in Fig. 3. The nonlinearity increases gradually to about 2%–4% until blooming or saturation sets in. The statistical error of this measurement is below 10^{-4}. The systematic error is driven by the thermal stability of the LED within a single exposure, and could amount to a few $\times 10^{-4}$.

These nonlinearity measurements were computed at discrete points, as depicted in Fig. 3. When the correction is applied, the correction factor between these points is calculated using linear interpolation. However, no correction is applied below 300 ADU because of high uncertainties in the calibration measurements at

Fig. 3. Pre-launch measurements of VIS nonlinearity based on ground testing for CCD 6-2. Each of the four lines corresponds to a separate quadrant. *Top panel*: measured intensity as a function of pulse time width. *Bottom panel*: linear signal divided by measured signal.

these low fluxes. We assume that the response is linear at these levels.

3.7. Cosmic ray flagging

The `LACosmic` algorithm (van Dokkum 2001) is used in VIS PF to flag CRs. However, the earliest *Euclid* images showed many CRs that were only partially flagged. In nominal VIS images, about 1.6% of pixels are flagged as CRs. The shapes of on-orbit CRs differ significantly from pre-launch expectations. In particular, there are many 'fat' CRs that were initially only partially flagged. Post-launch, to assess the best possible parameter set to correctly flag CRs and to assess performance, we created a series of simulated images based on real CRs detected in VIS dark frames. From these, we can assess the performance of different algorithms using the receiver operating characteristic (ROC) curves, which assess how well a model distinguishes between two classes by plotting the true positive rate (TPR) against the false positive rate (FPR) for a range of settings.

We follow the usual definition of the TPR, which is the ratio of the number of CRs that are actually detected to the number of actual CRs in simulation. Conversely, the FPR corresponds to the number of pixels that are incorrectly classified as CRs. The ratio is computed against the total number of pixels that are not actual CRs in the simulations. False positives (FP) are instances in which CRs are misclassified. An additional complication is that we must minimise the number of cores of non-saturated stars identified as CRs. After many simulations, we settled on the following set of parameters: `sigclip` = 10; `sigfrac` = 0.4; `objlim` = 20.0; `cleantype` = `medfilter`. This results in a TPR = 78.3% and an FPR = 0.03%, star FP = 1.1% (I_E < 20.0).

If more than 5% of pixels in a quadrant are flagged as CRs, all its pixels are flagged with the CR region identifier, `CR_REGION`. This way, we can mask the 'X-ray' pattern present on the VIS images during Solar flares (see Fig. 21 and Sect. 5.3
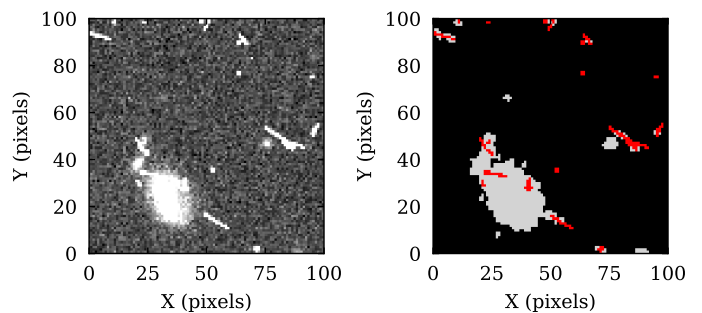

Fig. 4. Section of a VIS image (*left panel*) and the part of the associated flagmap (*right panel*). Grey pixels in the flagmap are objects and red ones are identified as CRs.

in Euclid Collaboration: Mellier et al. 2024). This enables other quadrants below the threshold to be used for scientific exploitation without having to discard the entire image.

3.8. Charge-transfer inefficiency

The performance of CCD imaging sensors gradually degrades due to radiation damage. High-energy particles create defects in the silicon lattice that trap photoelectrons from one pixel and release them after a delay, characterised by an emission time, τ. When this happens during readout, the electron is spuriously delayed into the wrong charge packet, appearing as if it were in a different pixel, and the image becomes smeared. Measurements from *Euclid* data indicate that faint sources are (fractionally) more affected than bright sources, as a constant number of delayed electrons has a greater relative impact. This effect is known as charge transfer inefficiency or CTI.

No correction for CTI has been applied to Q1 data. However, we are monitoring (Skottfelt et al. 2024) the growing density (ρ_i) of several trap species with characteristic emission time (τ_i). For a bright point source (with S/N = 200 following Israel et al. 2015) that might be used for PSF measurement far from the readout register, our model indicates that the net effect of parallel CTI at the end of May 2024 causes $\Delta F/F \approx -(3 \pm 2) \times 10^{-4}$ fractional flux loss, and $\Delta y \approx (2 \pm 1) \times 10^{-3}$ pixels of spurious astrometric shift, where uncertainties are the standard deviation between the best-fit value in every CCD quadrant. The damage in all quadrants is growing roughly linearly over time: with additional, abrupt damage during Solar coronal mass ejections coronal mass ejections (CMEs) and greater damage in the corner of the FPA that is also most exposed to radiation during CMEs. As the CTI 'signal' accumulates, these measurements are becoming more precise, and CTI correction will be activated for a future data release.

To monitor CTI, we use two techniques that both exploit a facility of the CCD electronics to inject precisely known patterns of charge.

– trap pumping (TP) works by electronically injecting a flat image of charge into the full device, then shuffling it forward and backwards repeatedly, using a fixed phase time (t_{ph}). If an electron is captured by a trap with $\tau \approx t_{ph}$, the repeated shuffling will produce a dipole pattern, as charge is released into an adjacent pixel. The intensity of this dipole can be modelled as

$$I(t_{ph}) = N P \left[\exp\left(-\frac{t_{ph}}{\tau}\right) - \exp\left(-\frac{2t_{ph}}{\tau}\right) \right], \tag{1}$$

where N is the number of shuffles and P is a measure of the 'efficiency' of the trap, that is how likely it is to capture a nearby electron. Since I is a function of t_{ph}, a dipole curve can be built up by repeating the TP process using different values of t_{ph}. By fitting this curve with Eq. (1), we measure τ and P for every trap. Doing this for the full FPA will thus provide information about the position and emission-time constants of the traps in the devices, supporting the CTI correction efforts.

– acEPER tests work by injecting rectangular regions of charge with sharp edges. We fit the trailing of electrons after each charge-injection block into pixels that should contain zero electrons. We model extended pixel-edge response (EPER) trails (in both parallel and serial directions) using a nonlinear model, `arCTIc` (Massey et al. 2010, 2014). However, to first order, their profile $I(x)$ is roughly a sum of exponentials

$$I(x) = \sum_i \rho_i \left[1 - \exp\left(-\frac{t_{cl}}{\tau_i} \right) \right] \exp\left(-\frac{t_{cl}}{\tau_i} x \right), \quad (2)$$

where x is the pixel number, and t_{cl} the readout cock speed in seconds per pixel. The prefactor in the bracket normalises the total number of trailed electrons to $\Sigma_i \rho_i$. First pixel response is the deficit of electrons in the leading edges of each charge injection block (in the opposite direction to the EPER trails). These electrons are the first to encounter empty traps, and many are captured (to eventually be released in the EPER trail).

3.9. Brighter-fatter effect

The BFE refers to the redistribution of charge within pixels as charge is accumulated (Downing et al. 2006; Antilogus et al. 2014). This is a consequence of the electric field of the charge; as more charge accumulates, pixel boundaries change. This effect depends nonlinearly on flux, and therefore causes the PSF to become larger for brighter stars. A secondary effect of the BFE is that as flux levels increase, the variance between pixels decreases.

To correct this effect, we compute a kernel to apply to the data. This kernel represents the deflection field of the accumulated charge for one pixel, and is represented by an 11×11 matrix. Simulations have shown these dimensions give the correction for the BFE. The BFE kernel is the solution of the Poisson equation with the pixel covariance as the source term. To compute the pixel covariance, a series of pairs of flat fields at high fluence with the same pointing are subtracted from each other, to remove the non-uniform illumination resulting from the calibration lamp profile. Since the shutter is open during flat-field exposures, the flat-field is immediately followed by a short science exposure to enable the masking of stars and other objects that are present in the flats. Finally, we mask allCRs and any bad pixels. The pixel covariance must be adjusted using a zero correction, which involves modifying the central pixel value of the covariance matrix to ensure that the total sum of all covariance values equals zero. This adjustment is performed before solving the Poisson equation to compute the BFE kernel.

This BFE kernel is used to correct the science image using an iterative flux-conserving approach. First, the image is converted to electrons and flagged pixels are 'inpainted' (where their values are replaced by nearby good pixels) to exclude them from the correction. The image is then convolved with the kernel to

compute a 'deflection potential'. At each iteration, the algorithm calculates the required pixel-to-pixel flux transfers from the gradients of this potential. Flux is conserved by ensuring that any charge redistributed from one pixel is added to nearby pixels according to the kernel's deflection field. This creates a correction image that is then added to the original to redistribute charge based on the BFE kernel. This procedure is repeated until the absolute difference between successive iterations drops below 10^{-6}. The image is the converted back to ADUs and inpainted pixels restored to their original values.

The photometric impact of the BFE correction on stars is shown in Fig. 5. Without BFE correction, the PSF core is broader for brighter stars. Consequently, in an aperture smaller than the scale at which the BFE is important, the flux ratio of identical stars in short and nominal exposures is smaller for brighter stars, as shown on the top panel of Fig. 5 from the ratio of the flux of the brightest pixel. This effect is visible mainly for stars with $I_E < 19$, and is not significant after BFE correction (bottom panel).

Figure 6 shows the impact of BFE correction on the PSF model derived with `PSFex` (Bertin 2011, see also Sect. 4.3) in terms of the Gaussian FWHM (left panel) and size in all quadrants before and after correction. To quantify the size, we rely on the squared radius R^2, as defined in equation (1) of Massey et al. (2013), based on the second moment method. More specifically, the quadrupole moments Q_{ij} are computed after weighting with a Gaussian function with $\sigma = 0\farcs75$. The squared radius R^2 is then given by

$$R^2 = Q_{11} + Q_{22}, \quad (3)$$

and it is compared to R^2_{ref} that is the size of a Gaussian profile with a FWHM of $0\farcs2$. While this correction decreases the FWHM, it leaves the PSF size unchanged on average, since this metric provides information on the PSF at scales larger than the BFE correction. However, the correction still reduces the spatial variations on the FPA (the standard deviation across all quadrants is smaller).
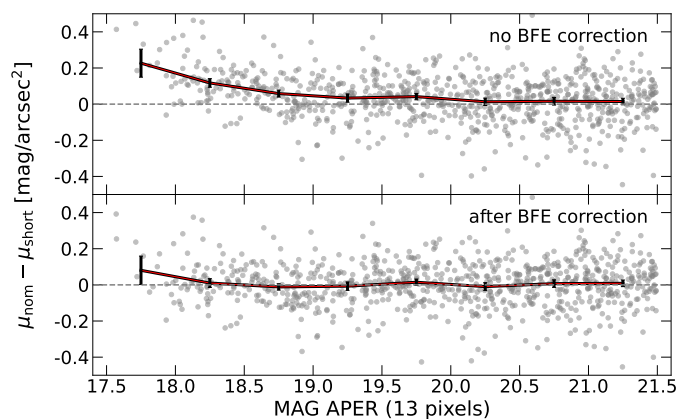

Fig. 5. Effect of BFE correction on the difference of the surface brightness of the brightest pixel of stars in nominal versus short exposures as a function of VIS magnitude in an aperture of 13 pixels or $1\farcs3$ diameter.

3.10. Pixel response non-uniformity

The pixel-response non-uniformity (PRNU) is defined as the relative response of a pixel compared to the average of its neighbouring pixels. Larger pixels created by small variations in the photolithographic mask used for fabrication will have a larger
Fig. 6. Effect of BFE correction on the PSF model, as quantified from the FWHM (*left panel*) and R^2/R^2_{ref} (*right panel*), which is the squared radius relative to that of a Gaussian profile with a FWHM of $0\rlap{.}''2$. There is one red marker per quadrant. The black markers and error bars indicate the mean and standard deviation across all quadrants.

response. The intrinsic and processed conditions of each pixel will also contribute to response differences. In *Euclid* detectors, the amplitude of this pixel-to-pixel variation is around 1%. The PRNU correction (using a flat-field image) attempts to remove the differential pixel-to-pixel response. Because the PRNU is both wavelength- and fluence-dependent, it is measured by illuminating the FPA with LEDs of four different wavelengths (573 nm, 592 nm, 638 nm and 697 nm) and three different fluences (10, 25, and 40 kADU). During this procedure, the shutter must be open so that the LED can illuminate the FPA, and consequently astronomical objects also appear. Therefore, for each fluence level, around 10 to 30 dithered exposures are taken.

When producing each master PRNU flat, each quadrant is examined for artefacts. All frames are corrected for crosstalk, bias, and nonlinearity. The shape of the illumination and the background is assumed to be stable to within the shot noise of the LED illumination. The master PRNU flat at each fluence is produced from a clipped combination of the individual exposures and divided by the illumination profile (fitted as a spline surface). This procedure works well except at the 10 kADU flats where some pixels from objects may remain. With this procedure, one master PRNU flat is produced for each combination of LED and fluence. The final cosmetic flagmap is a logical 'or' combination of all the individual master PRNU flagmaps for all wavelengths and fluences. The final 'small-scale' flat correction is the average of the four 10 kADU master PRNU flats per wavelength. Finally, since the PRNU is a multiplicative effect, it is corrected by dividing each image by this small-scale flat.

3.11. Background estimation

We compute the background for each VIS calibrated frame using the `NoiseChisel` program of GNU Astronomy Utilities (version 0.16; Akhlaghi & Ichikawa 2015) on each quadrant. By applying an initial threshold below the sky level and using mathematical morphology operators like erosion and dilation, this can detect very faint signal in the images and provide a very accurate estimate of the background (defined as the mean of pixels outside sources). This is especially important to preserve the low surface brightness signal in the stacked images and not oversubtract them as background. One particular point that needed to be addressed when running `NoiseChisel` on *Euclid* data is the extremely high density of CRs in some frames. To address this, all pixels flagged as CRs are set to not-a-number (NaN) before background estimation. `NoiseChisel` can ignore NaN-valued

pixels during operation, which allows us to make a sufficiently accurate estimate of the sky background even when the CR density was extremely high (15% of detected CR pixels).

Since the EWS continuously covers the sky, some VIS quadrants may see considerable signal, such as when imaging a large galaxy or cirrus cloud. This prevents `NoiseChisel` estimating the background to the desired precision. In such cases, `NoiseChisel` is run a second time with less restrictive run-time options. If the signal is so strong that the quadrant contained insufficient noise, the `SExtractor` background map is used instead. Consequently, there is some over-subtraction in the inner regions of objects that are larger than one quadrant. This problem will be addressed in future versions of VIS PF. Fortunately, such bright objects are rare and for most of the sky this strategy of a multi-tier `NoiseChisel` background estimation produces high-quality background maps and stacked images.

4. The VIS processing function: astrometric and photometric calibrations

4.1. Introduction

At the second level, quadrants are gathered and processed together, as illustrated in Fig. 7. Next, a series of calibrations are applied. The output products from this part of the processing chain comprise the Q1 data products.

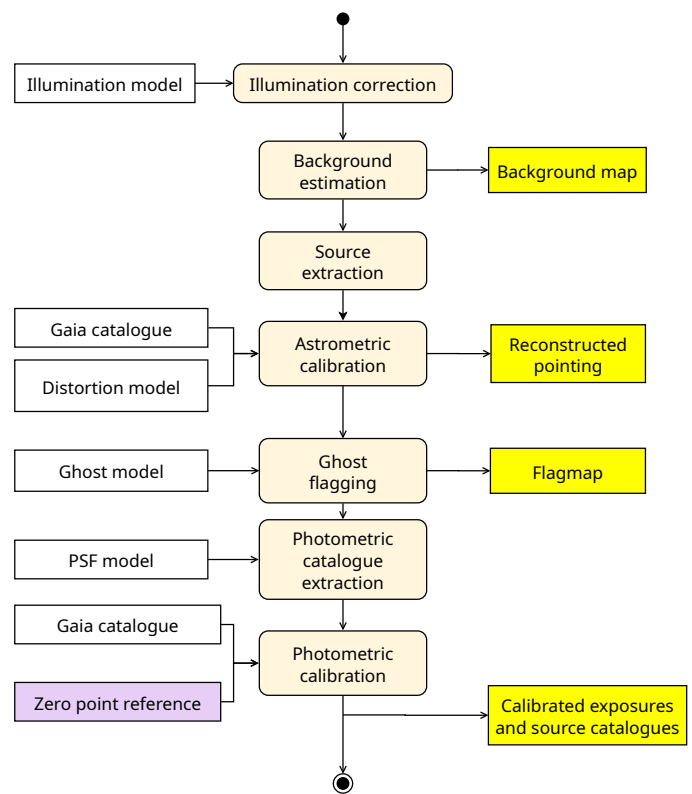

Fig. 7. Photometric and astrometric calibration and catalogue extraction. In this intermediate stage of the VIS PF, many operations take place at the catalogue level. The output products from this stage correspond to the data products that have been delivered for the Q1 release.

4.2. Gain equalisation

In VIS PF, we deliver images in ADUs. Each quadrant has a slightly different gain and so the final step is this part of the pro-
Fig. 8. PSF comparison. *Left panel*: The VIS PSF model delivered in Q1 in one quadrant, measured in the self-calibration field with `PSFex` at the VIS pixel scale. *Right panel*: a Gaussian PSF with a FWHM of 0″2. The red dashed circles indicate the PSF size defined from the second-moment method, described in the text.

cessing function is to apply a correction factor to equalise the gains. For Q1, the gain level is $3.48\,\mathrm{e^-\,ADU^{-1}}$. The correction factor is computed simply from the ratio of the individual detector gains and this reference gain.

We determine the gains for each quadrant from a series of nine pairs of 1 kADU flats. The difference images of each pair are combined with a clipping algorithm. Then, for each quadrant, we compute the gain as the average flux divided by half the variance of the pair difference in tiles of 300×300 pixels. The final gain is computed as an average over all tiles.

4.3. Point spread function characterisation

The highly detailed PSF model required for *Euclid*'s shear measurements is provided by the shear-measurement processing function (SHE-PF). In VIS PF, however, we derive a simpler model for monitoring and internal quality control purposes, referred to as the VIS PSF model. It does not consider the chromatic dependence of the PSF. This model is used by MER PF for photometric measurements on VIS images.

The VIS PSF is estimated using `PSFex` (Bertin 2011), which takes as input star positions and image stamps. The latter are 21 pixels wide, extracted with `SExtractor` around the windowed star centroids on short exposures of the monthly visits of the self-calibration or 'self-cal' field (Euclid Collaboration: Mellier et al. 2024). This field is located in the *Euclid* Deep Field North at $17^\mathrm{h}\,55^\mathrm{m}\,15^\mathrm{s}$, $65°\,17'\,8''$ and has a sufficiently high stellar density to monitor a range of instrumental effects, including PSF measurements.

`PSFex` optimally combines the input source images to enhance the PSF. More precisely, it iteratively computes the PSF model based on the star images, compares the images to the model reconstructed at the star position, and excludes the detections that are too discrepant with respect to the model. The output of `PSFex` is a PSF vector that encapsulates the spatial variation of the PSF across each quadrant, and in turn allows us to reconstruct the PSF model at any position. We assume here a second-order polynomial spatial variation of the PSF, modelled independently for each quadrant. Figure 8 shows the VIS model PSF in one quadrant compared to a Gaussian kernel with a FWHM of 0″2.

We compute the size, ellipticity, and FWHM of the model PSF to monitor its evolution with time and its variations across the FPA. First, the PSF centroid is determined iteratively, after weighting the PSF stamp with a Gaussian function having $\sigma = 0″75$. The FWHM is calculated as the azimuthal average of
Fig. 9. Stability of FWHM, size, and ellipticity of the VIS PSF model measured in the self-cal field. The red marker indicates the measurement on the Q1 VIS PSF model. The values are measured in each quadrant, and then averaged, and the error bars indicate the dispersion of the measurements across the quadrants. The thick red dashed lines correspond to the mission PSF requirements (Euclid Collaboration 2013). Regarding the PSF size, (Euclid Collaboration 2013) also specifies a "goal".
Fig. 10. Variations of ellipticity (*left panel*) and size (*right panel*) of the VIS PSF model across the FPA.

the width of the PSF at half maximum. Similarly to the squared radius R^2 defined in Eq. (3), the measurement of the ellipticity ϵ is based on the second-moment method, after weighting with a Gaussian function with $\sigma = 0″75$, and is given by $\epsilon = \sqrt{\epsilon_1^2 + \epsilon_2^2}$, with

$$\epsilon_1 = \frac{Q_{11} - Q_{22}}{Q_{11} + Q_{22}} \ , \quad \epsilon_2 = \frac{2Q_{12}}{Q_{11} + Q_{22}} \ . \tag{4}$$

Each month, a series of observations are made in the self-cal field. Here, a carefully chosen set of dither patterns ensures that each source is observed at various locations across the FPA.

The Q1 PSF model has been calibrated on data from March 2024 self-cal observations, immediately after the first decontamination campaign. Figure 9 shows the time variations of these metrics and compares them to the top-level mission requirement of *Euclid* (red dashed line). At the level of accuracy needed in VIS PF, these metrics are very stable, and meet the mission requirements. The FWHM and ellipticity are comparable to those estimated with `PSFex` in the Early Release Observations (see e.g., Cuillandre et al. 2024; Massari et al. 2024). In particular, the FWHM of the Q1 PSF model varies from 0″157 to 0″164 depending on the quadrant, with a mean over all quadrants at 0″158 and standard deviation of 0″001. We note that due to undersampling, the PSF model estimated with `PSFex` is generally slightly larger and rounder. Figure 10 shows the variations

of size and ellipticities over the FPA. These spatial variations are relatively stable in time.

4.4. Illumination correction

In successive exposures, an identical object placed at different locations across the VIS FPA will not have the same measured flux. The main cause of this effect is that the VIS shutter unit takes 2.7 s to open and close, which leads to a left-to-right gradient in measured fluxes. Because the shutter motion time is fixed, this means there is a roughly 6% left-to-right flux difference in short exposures and 1% flux difference for nominal exposures. Other factors leading to throughput variations across the FPA can include variations in optical elements such as mirrors, quantum efficiency variations between and within detectors, and errors in the gain estimation for each quadrant. The overall error in the uncorrected magnitudes is on the order of 0.05 mag in nominal exposures. This implementation described here is based on code and algorithms developed for the near-infrared processing function described in Euclid Collaboration: Polenta et al. (2025).

This large-scale flat field is derived from regular observations of the self-cal field (Sect. 4.3) by minimising the difference between the measured magnitudes of stars at all positions for 15 000 unique stars. Because the amplitude of the effect is small, creating the purest sample of unsaturated stars is essential. The large-scale flat pipeline takes as input `SExtractor` reference catalogues constructed using a PSF generated by running `PSFex` on the self-cal field (for the Q1 observations). We use the following selection criteria:

$$
\begin{array}{ll}
\texttt{spread\_model} & |\text{SPREAD\_MODEL}| < 0.005\,; \\
\text{Ellipticity} & \text{ELLIPTICITY} < 0.05\,; \\
\text{Flags} & \text{FLAGS} == 0\,; \\
\text{Signal-to-Noise} & \text{S/N} > 80\,.
\end{array}
\tag{5}
$$

The `spread-model` parameter (described in Section 3.2.7 in Desai et al. 2012) measures the amount by which the light profile of an object differs from a point source and can be used to robustly select point-like sources, see Fig. 16.

The large-scale flat provides characterises the relative illumination in a coarse grid of 3×3 tiles per quadrant. It is derived separately for short nominal exposures to account for the shutter effect on the effective exposure time. The final product of this calibration is a coarsely binned map of the FPA that contains a multiplicative correction that can be applied to all images, known as the 'large-scale' flat.

In Fig. 11 we show the large-scale flat correction derived for nominal and short exposures estimated from a combination of three successive visits of the self-cal field (taken on 10th June, 18th June, and 19th July 2024, respectively). In the left panel, the effect of the shutter movement on the measured signal is evident. For the nominal exposures in the right panel, the effect is less pronounced, as the ratio of the shutter movement time to the exposure time is correspondingly smaller and partially cancelled by the illumination in *Euclid*'s off-axis optical design (Euclid Collaboration: Mellier et al. 2024).

4.5. Astrometric calibration

The astrometric calibration begins with extracting a Gaia DR3 reference catalogue (Gaia Collaboration et al. 2023), which overlaps every VIS exposure footprint. Gaia sources with five- or six-parameter astrometric fits are moved to the epoch of each

VIS exposure, considering their proper motions and parallaxes. In addition, stellar aberration is incorporated using the spacecraft's orbital data added to the image headers by the ESA's mission operations centre. VIS catalogues are extracted from each image using `SExtractor` and bright, unsaturated stars are selected with $18.5 < I_\text{E} < 22$ and $16.7 < I_\text{E} < 22$ for nominal and short exposures, respectively.

To characterise the detector layout and distortion, an approximate initial world coordinate system (WCS) is available in the image header. This initial model is just the layout of the quadrants in the FPA, derived from the 'as specified' values in the mission database. It does not contain any rotation or distortion. This is typically sufficient to map pixel coordinates to equatorial ones to within a few arcseconds. This initial WCS means a positional cross-match between the VIS catalogue and the reference star catalogue is relatively straightforward.

Next, an initial model of the focal-plane layout and distortion ('FPA model') is fitted using a least squares algorithm. From here, an iterative process is adopted, involving rematching between the VIS and reference catalogues (with stricter requirements), leading to an improved FPA model. This process is repeated until either the required astrometric precision is attained, the reference source list does not change, or a set number of iterations is reached.

An FPA model is a nearly complete WCS, since it comprises reference pixel locations, a linear distortion matrix (CD$_{\rm I\_J}$), and Simple Imaging Polynomial (SIP; Shupe et al. 2005) distortion coefficients. The only difference with a standard WCS is that we use the individual detectors' centres for the reference-pixel coordinates instead of the centre of the FPA. This choice avoids large positional offsets and minimises the reduction in SIP model sensitivity that would occur if the FPA centre was used.

It is desirable to characterise detector distortion separately from WCS fitting, since not all exposures are expected to contain sufficient astrometric reference stars to measure the distortion with the required precision. SIP was adopted since it models distortion as a function of detector coordinates, which are static with respect to the expected sources of distortion. This contrasts with TPV,[3] which models distortion as a function of intermediate world coordinates, which is typically better suited to ground-based observations.

To compute the WCS for a given VIS exposure requires a previously computed FPA model that provides the basic detector layout and distortion model in the spacecraft-centric reference frame. The preliminary spacecraft pointing position and PA are used to produce an initial WCS from the FPA model, and these are used to generate preliminary sky positions for the detected VIS sources. These are then cross-matched to the reference catalogue, and the pointing and PA are then fitted using the least squares method. The process of cross-matching and pointing and position-angle refitting is repeated until either the required astrometric precision is attained, the reference source pool is static, or a set number of iterations is reached.

This procedure produces a WCS that maps detector coordinates into equatorial coordinates in the spacecraft-centric reference frame. The conversion to a WCS that maps to International Celestial Reference Frame (ICRF) coordinates is performed numerically using the spacecraft geocentric position and velocity. In the last step, the SIP WCS is converted to the more commonly used TPV convention and these WCS keywords are written to

---

Fig. 11. VIS large-scale flat for short exposures (*left panel*) and nominal exposures (*right panel*). The detector quadrants are easily discernable. This large-scale flat is computed by combining three successive visits of the self-cal field. For short exposures, the shutter effect on the measured signal is evident. The large-scale flat also corrects differences in the quantum efficiency and residual inaccuracies in the gain calibration, clearly visible for some quadrants.

each of the 144 image headers (one per quadrant) in the calibrated frames.

Figure 12 shows the difference between sources from the Gaia DR3 astrometric catalogue propagated to the *Euclid* Q1 observation epoch and sources on one of the Q1 images. The width of the distributions – measured as the median absolute deviation – is approximately 5.5 mas and 5.7 mas for RA and Dec, respectively.
Fig. 12. Astrometric residuals in a single image of the Q1 release. We show the difference between the position of Gaia sources propagated to the *Euclid* observation epoch. The width of the histograms, expressed as the median absolute deviation, are 5.5 mas (RA) and 5.7 mas (Dec). The colours represent the density of sources.

4.6. Photometric calibration

The photometric calibration process aims to produce calibrated magnitudes from instrumental magnitudes using reference sources. The initial absolute VIS photometric zero point calibration is computed based on 80 repeated measurements of the primary white dwarf spectrophotometric standard WDJ175318.65+644502.15 (Gaia SourceID 1440758225532172032) in short exposures in the self-cal field. On each image, thirteen-pixel diameter instrumental magnitudes are measured on short exposures. A curve-of-growth analysis is used to compute the correction to total magnitudes.

WDJ175318+6445 is part of a set of faint hot white dwarfs that were observed both photometrically and spectroscopically with WFC3/IR and STIS (Cycle 29 and 31) on the HST. By combining GALEX, Gaia, and the HST WFC3/IR data, the spectral energy distributions (SEDs) were fit with a grid of hot white dwarf templates. The best-fitting template was used to provide preliminary (1 – 2% precision) synthetic VIS (and NISP) magnitudes. These SEDs will be refined over the coming months by combining the previous HST data with new STIS observations of the stars. More details can be found in Appleton et al. (in prep.) and Deustua et al. (in prep.). Over the course of the *Euclid* mission, it is expected that more calibration sources will be observed to further improve the accuracy of *Euclid*'s absolute calibration, which is directly linked to the HST CALSPEC database (Bohlin et al. 2017).

Soon after launch, it was realised (from comparisons of sources in the self-cal field observed at successive dates) that telescope throughput was steadily decreasing due to the build-up of water ice on the mirrors in *Euclid*'s instrument cavity. This was expected and is common in spacecraft (Euclid Collaboration: Schirmer et al. 2023). A first thermal decontamination campaign was carried out on 12 March 2024 when folding mirror 3 (FoM3) and the tertiary mirror (M3) were heated to 160 K (for the telescopic design see Euclid Collaboration: Mellier et al. 2024). This restored the throughput to levels observed immediately after launch. However, the throughput rapidly dropped once more. After a second decontamination campaign on 6 June

2024, heating FOM3 only, the throughput returned to immediate post-launch levels and has remained stable since.

These variations in observed throughput indicate that a single photometric zero point is inadequate, especially when throughput changes rapidly, such as between the two decontamination campaigns. We therefore developed an alternative method to compute the zero point for each exposure using a direct comparison with Gaia photometry.

We take G as the Gaia G-band magnitude, and G_{BP} and G_{RP} are the Gaia blue and red magnitudes, respectively. The colour term C is defined as

$$C = G_{BP} - G_{RP} - 0.3406,\qquad(6)$$

where the constant term transforms to the AB magnitude system (Oke & Gunn 1983). The VIS I_E magnitude is then

$$I_E = G + 0.1136 - \left(p_0 + p_1 C + p_2 C^2 + p_3 C^3 + p_4 C^4\right),\qquad(7)$$

with

$p_0 = -0.00489071,$

$p_1 = 0.405557,$

$p_2 = -0.0256434,$

$p_3 = -0.0627437,$

$p_4 = 0.0204569.$

These Gaia-derived zero points allow us to monitor the VIS throughput and compute zero-points even for data that are affected by ice. For Q1, the photometric calibration was computed by calculating the median of all individual zero point measurements from July 1st to September 1st 2024. This value (in ADUs) is 24.57 s^{-1}.

For nominal and short exposures, we select sources with $18.5 < I_E < 19.8$ and $16.5 < I_E < 19.8$ respectively. We use the `spread-model` parameter to select point-like source as before Sect. 4.4. For each source, object photometry is performed using 13 pixel diameter circular apertures (corresponding to $1\farcs3$). We apply a correction factor to these magnitudes to arrive at 'total' magnitudes which contains most of the object flux (the correction factor is computed by comparing fluxes in 13-pixel and 50-pixel apertures for non-blended stars over the FPA; it is available in the header of each image in the `APERCOR` keyword). The zero-point is computed from a clipped estimate of the median difference between these VIS instrumental magnitudes and the predicted Gaia VIS magnitudes for Gaia stars with $0 < C < 2.5$.

4.7. Ghost flagging

The dichroic mirror (Euclid Collaboration: Mellier et al. 2024) separates visible and infrared light in *Euclid*. The nominal light path of VIS is reflected at the dichroic's front surface. A small fraction of the photons, however, is reflected at the back surface. The additional optical path length leads to out-of-focus ghost images of bright stars ($I_E < 14$) in the VIS focal plane. The attenuation factor is about 10^{-6} over the ghost area. The ghosts are offset a few hundred pixels from the star's position. An example ghost image is shown in Fig. 13.

A model of the ghost offset as a function of its source star position in the FPA has been built using in-flight science images. It predicts the position and brightness of the dichroic ghosts. No attempt is made to model and subtract the ghosts themselves, as their surface-brightness distribution is rather complicated and chromatic. Pixels affected by a ghost are included in the image's flag map based on a simple flux threshold. We note that this step can only be carried out after the astrometric solution is made.
Fig. 13. An example of a VIS optical ghost from a bright star with I_E =5.5. The flux in the ghost pixels is around 3000–4000 ADUs above the background.

5. The VIS processing function: stacking and catalogue extraction

Figure 14 shows the final stage of the VIS PF. Stacked images and catalogues derived from these stacked images are not delivered as part of Q1, but they are described here in the interest of completeness.
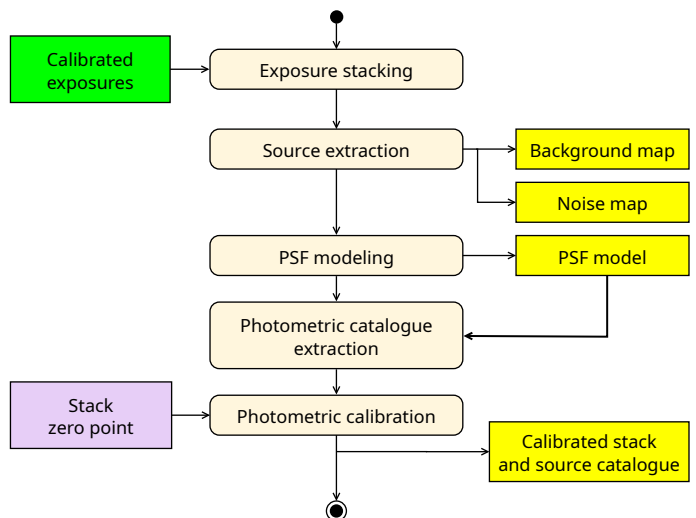

Fig. 14. The final processing elements of VIS PF that produces stacked images and catalogues.

5.1. Stacking

In the final processing steps, individual VIS calibrated frames and their associated weight maps are combined using the image resampling and co-addition software `SWarp` (Bertin et al. 2002). Figure 15 shows a single VIS image (left panel) and a stacked image, combined from six VIS images, four nominal exposures and two short exposures (resulting in a total exposure time per pixel of 2422 s). This stacked image has a 10σ depth of $I_E = 25.6$, computed as the variance of $1\farcs3$ diameter apertures, chosen to represent extended objects. This compares very

favourably with the top-level *Euclid* requirement of $I_\mathrm{E} = 24.5$. Together with the stacked image, a weight map is also generated.

We note that most Q1 papers use MER stacked tiles and catalogues. These tiles are made by MER from VIS images combined with an RMS map, where bad pixels are weighted accordingly. The stacked images produced by VIS and described here, covering the full FPA, are not used in the downstream processing.

5.2. Catalogue extraction

We extract catalogues using SExtractor (Bertin & Arnouts 1996) from the stacked images using the PSF model and weight map derived above.

6. Automated quality control

The VIS PF is executed on all data, even bad or incomplete images. For each VIS calibrated frame, an xml file is produced containing quality assessment information, in addition to a json file that contains fine-grained quality control information for each of the 144 quadrants. A list of the data-quality control statistics provided is given in Appendix B. They are described in the following sections.

6.1. spread_model measurements

During commissioning, the spread-model parameter was found to be highly correlated with the presence of guiding errors. In VIS PF, the FPA_spreadmodel_peak parameter represents the peak of the distribution in flux_auto versus spread_model for objects in the range

$$1.5 < \log_{10}\left(\frac{\texttt{FLUX\_AUTO}}{\texttt{FLUXERR\_AUTO}}\right) < 2.5 \tag{8}$$

where FLUX_AUTO and FLUXERR_AUTO are an estimate of the total flux with the Kron radius (Kron 1980).

Figure 16 shows spread_model against SNR (top panel) together with a histogram of spread_model values with the best-fitting Gaussian overlaid in orange. The locus of unresolved sources at spread_model at ~ 0 is clearly visible. Using PV data, and comparing with spacecraft housekeeping and telemetry data, we determined that spread_model peak values above 0.002 correspond to data affected by guiding errors. The FPA_spreadmodel_sigma is the standard deviation of the Gaussian fit described above.

6.2. Image score

A second image quality metric, the 'score' is computed for each exposure using image postage stamps extracted with SExtractor. We compute the median sizes R^2 and ellipticities (ϵ_1, ϵ_2) of high-S/N stars[4] across the FPA, derived from second moments weighted by a $0\farcs25$ standard deviation Gaussian aperture (see Eqs. 3 and 4. We note that a smaller standard deviation is used to mitigate the impact of CRs).

The score expresses how much these values deviate from the typical exposure-to-exposure scatter, as determined from the

---

[4]Stars with peak fluxes at least 10% of the pixel saturation limit are used.

fine-guidance test campaign during PV observations in September 2023. Because guiding errors are larger in the Y direction than in X, the R^2 and ϵ_1 values are anti-correlated. The score is computed as:

$$\mathrm{Score} = \boldsymbol{V} \cdot \mathsf{C}^{-1} \cdot \boldsymbol{V}^\mathrm{T}, \tag{9}$$

where

$$\boldsymbol{V} = \left(R^2 - R_\mathrm{ref}^2, \ \epsilon_1 - \epsilon_{1,\mathrm{ref}}, \ \epsilon_2 - \epsilon_{2,\mathrm{ref}}\right), \tag{10}$$

with the reference values

$$R_\mathrm{ref}^2 = 1.923\,\mathrm{pixels}^2, \quad \epsilon_{1,\mathrm{ref}} = -0.02313, \quad \epsilon_{2,\mathrm{ref}} = 0.00273. \tag{11}$$

The covariance matrix is given by

$$\mathsf{C} = 10^{-6}\begin{bmatrix} 542.2 & -118.4 & 0 \\ -118.4 & 44.88 & 0 \\ 0 & 0 & 5.332 \end{bmatrix}. \tag{12}$$

As the VIS PSF is chromatic due to the dichroic beam splitter and the wide VIS bandpass, when observations are made with a population with an atypical colour distribution, the median second moments and therefore the score will be affected. Currently, this colour dependence is not accounted for, as the score mainly serves to identify suspect images. All images with a score greater than 60 undergo a quality control check. Large score values indicate either a proton shower – which affects the automatic star selection or the second moments – or a tracking failure.

### 6.3. Other quality control statistics

Finally, we compute several other quality control statistics. From maps of CRs detected by LaCosmic (Sect. 3.7) we compute FPA_max_cr and FPA_fpa_cr, which are the percentage of pixels flagged as CRs in the most affected quadrant and the average percentage of CRs over the FPA, respectively. We also compute the mean astrometric residual over the FPA, computed from the difference between the positions of sources in the FPA with their counterparts in Gaia DR3 propagated to the epoch of observation.

7. Q1 validation

7.1. Q1 data quality control

The Q1 release includes 852 VIS images in four fields: the Euclid Deep Field North (EDF-N), Euclid Deep Field South (EDF-S), Euclid Deep Field Fornax (EDF-F) and single pointing in the Lynds Dark Nebula LDN1641 ("Dark Cloud", see Euclid Collaboration: Aussel et al. 2025). The Q1 data release contains only data at the depth of the EWS, except for the Dark Cloud, which is deeper.

Applying the data-quality control flags described in Sect. 6 to the Q1 VIS data, we rejected 16 exposures (1.9 %). An exposure is discarded if any of the following conditions are met: (i) one of the three criteria (spread_peak, score, or astrometric residual) is met, (ii) all quadrants are masked by the CR_REGION flag, or (iii) the zero point cannot be computed. Figure 17 shows the distribution of Q1 quality control flags, with the dotted line indicating the threshold above which an image is considered potentially unusable. The effect of this image rejection procedure can be seen in the coverage map in the bottom right-hand panel of in figure 3 in Euclid Collaboration: Aussel et al. where shallower depths are a consequence of the rejection of two images affected by guiding errors.
Fig. 15. Part of VIS images in the Q1 data. *Left panel*: an individual VIS calibrated frame. *Right panel*: a stacked image of the same sky region, comprising six combined VIS images (four nominal and two short) for a total exposure time per pixel of 2422 s.

Fig. 16. `spread_model` values for a nominal Q1 exposure. The top panel shows a two-dimensional histogram of `spread_model` against SNR (defined as the ratio of `FLUX_AUTO` to `FLUXERR_AUTO`). The colour scale corresponds to the density of points. The bottom panel shows the histogram of `spread_model` values, with the best-fitting Gaussian overlaid in orange.

7.2. Making the merged stellar catalogue

In this section, we consider the photometric and astrometric characteristics of these data by analysing the 836 VIS calibrated frame catalogues produced by VIS PF. These catalogues are extracted from both nominal and short exposure data. Although some of these statistics presented here are computed on an image-by-image basis as part of the normal VIS processing, the aim is to determine the ensemble properties of the entire Q1 dataset and in particular to investigate the characteristics of objects that have been observed multiple times in separate exposures.

VIS PF provides the catalogues as MEF files, each with 144 extensions, one for each quadrant. We read each quadrant and compute the position on the VIS focal plane (x, y) in millimetres
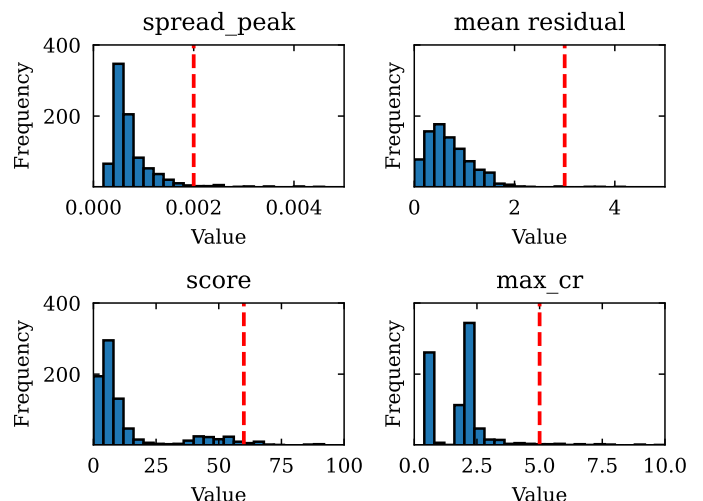

Fig. 17. Distribution of `spread_peak`, `score`, `mean_residual` and `max_cr` for all the 852 Q1 VIS images. After the application of these quality control statistics, 836 images remain.

for each source (this quantity is not present in the Q1 catalogues but will be available in the future), as well as adding a quadrant identifier `CCD_QUADID`. The final product is a single catalogue combining all quadrants. Next, we isolate a sample of unsaturated stars in both short exposures and long exposures using the `FLUX_RADIUS` – aperture magnitude (in 13 pixel diameter) relation. We select stars for both exposures using the following criteria:

$$\text{Selection mask:} \quad 1.0 < \texttt{FLUX\_RADIUS} < 1.3, \tag{13}$$
$$\texttt{FLAGS} = 0.$$
$$\text{Short exposures:} \quad 16.5 < \texttt{mag} < 21.0, \tag{14}$$
$$\text{Long exposures:} \quad 18.5 < \texttt{mag} < 22.0. \tag{15}$$

Finally, for each catalogue, these stars are matched to the Gaia DR3 catalogue using a $0\rlap{.}''2$ matching radius. Using the

Gaia DR3 proper motions, we compute the necessary correction to proper motion for the matching VIS stars. Next, we positionally merge the matched Gaia-VIS catalogues created above from all observations into a single master catalogue. This catalogue contains all the VIS observations for both short and long exposures for each star. We apply an additional criterion that each group must contain only objects from different `CCD_QUADID` and from different exposures. The dither pattern in the EWS is large enough to ensure that most object groups contain three or four observations. Unless otherwise noted, all the tests described here use only the long exposures, although we find no significant differences with the short-science exposures.

7.3. Astrometric accuracy of the merged Q1 catalogues

Using the merged catalogue described above, for each group we compute the mean (x, y) position and the mean astrometric coordinates, (`ALPHAWIN_J2000`, `DELTAWIN_J2000`). Next, these mean positions are binned on the focal plane in a 12×12 grid and median residuals with respect to Gaia are computed corresponding to the square root of the sum of the squares of the residuals in RA and Dec. This is shown in Fig. 18. These residuals are smaller than 8 mas. Over all exposures, the standard deviation of the residuals in RA and Dec is 7 mas and 8 mas respectively. We find that the residual field exhibits a non-zero curl. This is because the Q1 distortion matrix has not been updated since the PV phase. Since the Q1 processing described here, we have reprocessed larger datasets with a distortion matrix recomputed from the self-cal field at the appropriate epochs, and the circular pattern is no longer present.

Fig. 19. Median internal astrometric precision over the focal plane for nominal validated exposures in Q1.

7.4. Photometric scatter between observations

Next, using our merged catalogue, we investigate the photometric scatter between multiple observations of the same object in the nominal exposures over all Q1 data. This is shown in Fig. 20. The dashed blue line line shows the photometric requirement, and the shaded background the distribution of points as a two-dimensional histogram. For each group of observations, the relative flux error is computed as the group's standard deviation normalised by the group's mean flux and plotted as the solid red line. Over the magnitude range considered, the relative flux error in percent ranges from 0.6% to 0.7%, well within the 1% requirement.

Fig. 18. Median absolute astrometric precision over the focal plane for validated nominal exposure in Q1 release. Each square denotes the median difference between Gaia stars precessed to the *Euclid* observation epoch and the VIS positions.
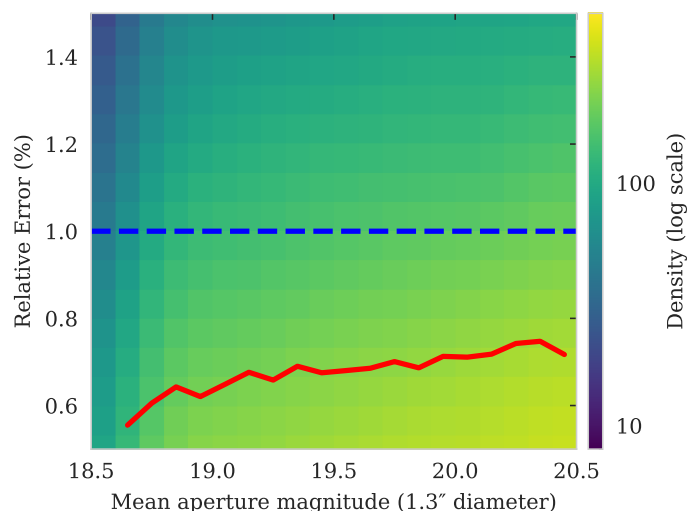

We also compute the same statistics internally, this time comparing the positions of the same sources on multiple exposures, shown in Fig. 19 (note that the scale of the length of the arrows is not the same between the two plots). We note that the registration over the separate exposures is much better than 1 mas over most of the field.

Fig. 20. Photometric scatter as a function of 1″3 diameter aperture magnitudes for validated nominal exposures in Q1. The shaded background shows the number of points as a two-dimensional histogram, with lighter-coloured regions corresponding to more objects.

As an additional check, we cross-matched the Q1 MER photometric catalogue (Euclid Collaboration: Romelli et al. 2025) with this catalogue. We compared the mean 13-pixel diameter aperture flux of each object in each group (corrected to total magnitudes using the `APERCOR` factor described in Sect. 4.6)

with the MER total magnitudes. At $I_E < 19.5$ we find that these corrected magnitudes agree with MER fluxes to within 1%.

7.5. VIS galaxy counts

Finally, Fig. 21 shows the galaxy counts for the four different sky patches, computed using the `mag_auto` magnitudes extracted from the stacked images. Counts are computed in half-magnitude bins normalized to per square degree. Galaxies were selected from the catalogues by imposing a size (≥ 1.25 times the PSF size) and signal-to-noise (≥ 10) requirement to mimic the object selection for cosmic shear measurements.

The Dark Cloud region has lower counts because of heavy dust obscuration. In the remaining three Euclid Deep Fields (North, South, and Fornax), the galaxy counts are in excellent agreement, with the turnover magnitudes differing slightly. The turn-off is at fainter magnitudes where the zodiacal sky background is the lowest, or the furthest away from the ecliptic plane. EDF-N is at the north ecliptic pole, and the ecliptic latitude is lower for EDF-S and EDF-F.

The cumulative galaxy counts at $I_E = 24.5$ are around 30 arcmin^{-2}, meeting the general *Euclid* requirement. Our catalogues can be considered complete here, given that the counts turn over at much fainter magnitudes. We also compare with counts computed using a special version of the COSMOS2020 catalogue (Weaver et al. 2022) where the I_E flux of each source has been computed from the best-fitting spectral energy distribution (SED) following the methods outlined in Saito et al. (2020). The agreement is excellent, especially given that our area computation does not account for area lost by bright stars or image artifacts.

We note that in the stacked images (whether by VIS PF or by the downstream MER PF), the survey depth varies across the image, with the depth variation dominated by the number of nominal exposures. The bulk of the wide survey consists of pointings with three or four nominal exposures. Analysis of the EDF-N field catalogues shows that the turnover point for the three- and four-image stack depths differs by ~ 0.2 mag, and the EDF-N counts in Fig. 21 lies between the three- and four-image stack curves. This same behaviour has been observed in shallower ecliptic latitudes with more Zodiacal light than in EDF-N.

8. Known caveats

As part of the Q1 validation process, we compared the fluxes of identical sources in both short and nominal exposures. Fluxes were normalised to the exposure times reported by the `EXPTIME` header keyword, and then compared between short and long exposures. This test indicates that the fluxes in the normalised long exposures are approximately 2% lower than in normalised short exposures. As described in Sect. 4.4, the exposure time across the FPA is non-uniform because of the shutter function. This non-uniformity is corrected for by the respective short-exposure and nominal-exosure large-scale flats constructed from relative stellar photometry. However, in the Q1 dataset described here, the absolute normalisation of the large-scale flat is the average exposure time of the FPA, which does not consider the relative flux differences induced by the shutter. For future releases, we will first scale the fluxes between the short and nominal exposures to remove this discrepancy. Second, once an accurate shutter-movement model is available, we will remove the shutter-dependent exposure time variation from the short and nominal exposures, and the flux differences will disappear.
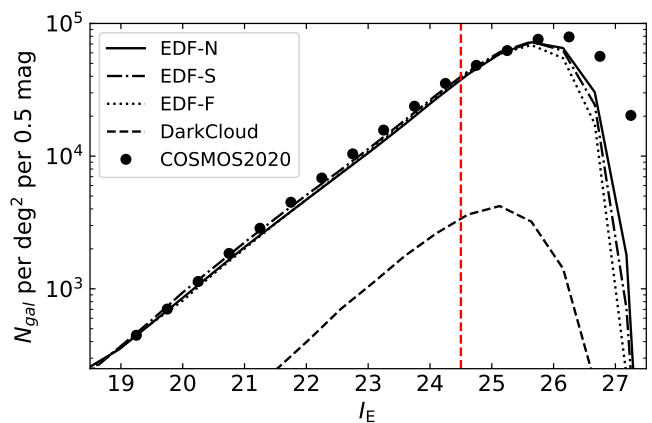

Fig. 21. Mean magnitude histogram of galaxy counts per square degree from VIS stacks (a single pointing containing four nominal and two short exposures). The mean is given separately for each of the sky patches of the Q1 release, and each is an average of around 40 stacks. The bin width is 0.5. Galaxies were selected according to a minimum size (≥ 1.25 times the PSF size) and signal-to-noise (≥ 10). Each VIS stack covers approximately 0.6208 deg^2. The COSMOS galaxy counts are based on estimated I_E magnitudes, by fitting SEDs over all the COSMOS bands.

We also compared the MER photometric catalogue (Euclid Collaboration: Romelli et al. 2025) with the calibrated frames presented here. We compared the mean flux of each object, measured within a 13-pixel diameter aperture, of each object in each group (corrected to total magnitudes using the `APERCOR` factor as described in Sect. 4.6) with the MER total magnitudes. For sources with $I_E < 19.5$ we find that these corrected magnitudes agree with MER fluxes to within 1%. The origin of this discrepancy is under investigation, but this test provides a useful upper limit on the magnitude of the effect described above on the final photometric measurements.

9. Conclusions

This paper presents the automatic pipeline that has been developed to process data from *Euclid*'s VIS camera, VIS PF. This software computes master calibration data for instrumental effects present in VIS data and uses these calibration products to produce science-ready data from raw VIS images. The VIS PF also provides a detailed set of quality control parameters and flags for each image that allows robust data selection to be made at both the image and pixel level. We demonstrate the performance of VIS PF on data taken during the PV phase in August 2023 and show that the principal mission requirements are met. We describe the VIS Q1 data release, and show the excellent quality of the processed and validated Q1 data. Images have a highly stable 0.″16 FWHM and the image-to-image photometric scatter is less than 1%. The processed VIS images (and the associated science papers in this Q1 data release) provide a glimpse of the revolutionary science that these wide-field high-resolution images will achieve.

Appendix A: A brief description of VIS Q1 data products

Q1 products are distributed through the Euclid Science Archive (SAS).[5] VIS Q1 products are fully described in the data product description documentation.[6] The SAS includes both processed and raw VIS images from nominal and short exposures. Catalogues extracted from the calibrated frames are also provided. Both Catalogues and images are delivered in the FITS (Wells et al. 1981; Pence et al. 2010) format.

Appendix A.1: The VIS calibrated quad frame

In the VIS calibrated quad frame[7,8] data product, three kinds of FITS files are supplied. In each file, the quadrant arrangement follows Fig. 1. The DET (for 'detrended') MEF file contains three extensions SCI, RMS and FLG for each of the 144 quadrants. The SCI extension corresponds to the VIS science image. Both nominal and short exposures are supplied, in ADUs with a gain of $3.48\,e^-$ for each quadrant and a zero-point of $24.57\,s^{-1}$.

The RMS extension is a noise map constructed by summing in quadrature the science image photon noise and quadrant readout noise (both in electrons), then converting the total to ADUs.[9]

The FLG[10] extension is a quality-control image delivered as a signed integer. The INVALID is a convenience flag that contains most of the bad regions listed below. The code snippet below shows how to read this file and select only object pixels suitable for science (good_objects).

```
with fits.open(fits_file) as hdul:
    flag_array = hdul[3].data.astype(np.int32)

# Define bad flags with their meanings
bad_flag_definitions = {
    0: "INVALID", 1: "HOT", 2: "COLD",
    3: "SAT", 4: "COSMIC", 5: "GHOST",
    7: "BAD_COLUMN", 8: "BAD_CLUSTER",
    9: "CR_REGION", 12: "OVRCOL",
    15: "CHARINJ", 17: "SATXTALKGHOST",
    21: "ADCMAX", 22: "NO_DATA"
}

bad_flags = sum(1 << i for i in
    bad_flag_definitions)  # Combine all bad
    flags
invalid_flag = 1 << 0  # INVALID flag

object_flags = (1 << 18) | (1 << 24)  #
    STARSIGNAL, OBJECTS

# Identify pixels that are objects
```

```
is_object = (flag_array & object_flags) != 0  #
    True for OBJECTS or STARSIGNAL pixels

# Identify pixels that are not marked as
    INVALID

is_valid = (flag_array & invalid_flag) == 0
good_objects = np.logical_and(is_object,
    is_valid)
```

Listing 1. Example code to select object pixels unaffected by invalid pixels (including a full flag list).

Finally, two additional FITS files are supplied: the weight map and background map (indicated by WGT and BKG in the filename). The weight map is simply the small-scale flat (Sect. 3.10) where all pixels flagged as INVALID are set to zero. The background file is the NoiseChisel (Sect. 3.11) background map.

Appendix A.2: The VIS calibrated quad frame catalogue

The VIS calibrated quad frame catalogue is a FITS table catalogue with 144 extensions produced by SExtractor. The Data Product Description Document (DPDD) provides a complete list of parameters that are almost all standard SExtractor parameters, except for calibrated flux measurements in microjanskys, which are indicated by the suffix _CAL.

Appendix B: Image quality control statistics

Each VIS calibrated frame is supplied with an xml file that contains the following quantities:

- **FPA_spreadmodel_peak** – the peak of the spread_model distribution (Sect. 6.1);
- **FPA_spreadmodel_sigma** – the width of the spread_model distribution (Sect. 6.1);
- **FPA_max_cr** – percentage of pixels impacted by CRs in the most affected quadrant (Sect. 6.3);
- **FPA_fpa_cr** – average percentage of pixels flagged as CRs over the FPA (Sect. 6.3);
- **FPA_cr_regions** – the number of quadrants masked by the CR_REGION flag (the number of quadrants where more than 5% of pixels are flagged as CRs);
- **FPA_mean_residual** – The mean astrometric residual averaged over the FPA;
- **FPA_e1_med** – the median value of ϵ_1 of selected stars (Sect. 6.2);
- **FPA_e2_med** – the median value ϵ_2 of selected stars (Sect. 6.2);
- **FPA_r2_med** – the median value of the R^2 of selected stars (Sect. 6.2);
- **SCORE** – the overall image quality score (Sect. 6.2).

Appendix C: Configuration files

For the SExtractor configuration, most parameters were kept close to their defaults. Aperture photometry is measured in four apertures of 7, 13, 26 and 50 pixels in diameter. DETECT_THRESH was set to 1.5. For PSFEx, we chose BASIS_TYPE=PIXEL_AUTO and PSF_SIZE=21,21 and fitted the PSF variation with a second-degree polynomial with PSFVAR_DEGREES=2.
